Abstract

We study the effectiveness of the ECB’s negative interest rate policy on the yield curve with a new shadow-rate term structure model. Our model captures the discrete nature of the policy rate and a non-constant spread between it and the short end of the government bond yield curve. We price bonds with forward-looking agents, and find all modeling components are crucial to match the yield data and generate sensible economic implications. We find a 10 basis-point drop in the lower bound lowers the short rate by the same amount, and lowers the 10-year yield by 6 to 8 basis points.

Keywords: effective lower bound, negative interest rates, shadow-rate term structure model, regime-switching model

1 Introduction

The effective lower bound (ELB) is one of the most discussed economic issues of the past decade. Central banks around the world repeatedly lowered their policy rates until they reached the zero lower bound (ZLB) in order to stimulate their economies as a response to negative shocks like the global financial crisis of 2007 - 2008. Zero was considered the lower bound for interest rates until recently when several central banks – the European Central Bank (ECB), Danmarks Nationalbank, Sveriges Riksbank, Swiss National Bank, and Bank of Japan – adopted negative interest rate policies as a means of further encouraging investment and lending among financial institutions. For example, by the end of 2016, the deposit rate of the Swiss National Bank hit a record low of -0.75%, while the European Central Bank (ECB) lowered it to -0.4%.

What are the economic implications of negative interest rates? Do they provide the additional monetary easing that these economies need? Much of the existing literature has focused on whether and how much negative interest rate policy has affected banks’ profitability; see, e.g. Jobst and Lin (2016) and Coeuré (2016). Our paper evaluates this policy’s impact on the yield curve which links financial markets and the macroeconomy. Understanding these questions is important to European countries and Japan, which are currently experiencing the ELB. It is also important for the US economy, for which the ELB remains an option in case of large negative shocks.

We develop a new shadow-rate term structure model (SRTSM) to describe the current economic environment with negative interest rates. We apply our model to the Euro area, and investigate the effect of a change in the ELB on the yield curve. We find a 10-basis-point drop in the ELB lowers the short end of the yield curve by the same amount. However, the effect is dampened at longer maturities, and it decays to 6 to 8 basis points for the 10-year yield.

The innovation of our model is the time-varying lower bound for interest rates, which consists of three main ingredients. First, agents are fully forward looking and incorporate
their expectations about future movements in the lower bound when they price bonds. We are the first to introduce the forward-looking aspect of the time-varying lower bound into a model. This is crucial both theoretically and empirically. Forward-looking decision-making is arguably the most important building block of modern finance. A model with a time-varying lower bound would be internally inconsistent if agents in the model were naive, never updated their beliefs, and always thought the lower bound would stay where it currently was even after seeing it move repeatedly. Empirically, we find models with forward-looking agents fit the data better. More importantly, a model with myopic agents implies larger effects of changing the lower bound on long term yields.

Second, we document a non-constant spread between the overnight policy rate and the short end of the government bond yield curve, and incorporate it into our model. This empirical fact has been overlooked in the term structure literature. The short rate was higher than the deposit rate from mid 2013 to early 2015, and the difference was as large as 20 basis points. Since early 2015, the short rate - deposit rate spread has become negative and has grown over time. By the end of 2016, the difference became -60 basis points. A potential explanation for this negative spread toward the end of our sample is that government bonds issued by countries such as Germany and France are often posted as collateral for short-term borrowing in repo markets, and excessive cash in these economies leads to scarcity of these assets. Ignoring this inherent feature of the data could lead to a very poor fit.

Third, we devise a regime-switching process to capture the discrete nature of the deposit rate, which allows us to preserve an analytical approximation for the pricing formula despite the additional flexibility introduced to accommodate the time-varying lower bound. Analytical bond prices make the model tractable and alleviate some numerical burdens. Dynamic term structure models are often criticized for their numerical behavior. If we had to compute bond prices numerically, the model would behave worse. We compare our model to several alternatives including popular specifications found in the literature. We find our proposed model performs the best in terms of higher likelihood, lower AIC and BIC, and lower pricing
errors. Both of the newly proposed modeling components are crucial to fit the forward curve or yield curve. The existing models in the literature, on the other hand, do poorly.

The implied shadow rate tracked the policy rate and the short end of the yield curve before the ELB was binding. It fluctuated between 0 and -1% when the policy lower bound was kept constant at zero. Subsequently, the ECB lowered the deposit rate at 10 basis-point intervals to -40 basis points. During this period, the shadow rate trended down, dropping from -1% to as low as -5%. Term premia for the Euro area were higher between 2004 and 2008, and have trended down since 2009. Negative term premia emerged at the ELB, potentially due to QE purchases.

After a brief literature review, the rest of the paper proceeds as follows. Section 2 presents some simple empirical evidence on the relationship between the lower bound and yield curve. Section 3 sets up the new SRTSM. Section 4 lays out the details for the time-varying lower bound. Section 5 describes the estimation, Section 6 discusses empirical results, and Section 7 concludes.

**Literature** Earlier work has applied the SRTSM mostly to the Japanese and US yield curve. For example, Kim and Singleton (2012) and Ichiuie and Ueno (2013) focus on Japan, whereas Krippner (2013), Christensen and Rudebusch (2014), Wu and Xia (2016), and Bauer and Rudebusch (2016) focus on the United States. These papers kept the lower bound at a constant level.

A few studies have worked on the new development in Europe, where the policy lower bound kept moving down to negative numbers after it entered the ELB. For example, the online implementation of Wu and Xia (2016) for the Euro zone, and Lemke and Vladu (2016) and Kortela (2016). However, none of these papers allow agents to be forward-looking in terms of the lower bound. Moreover, the literature completely overlooks the non-constant spread between the policy rate and the government bond yield curve. We show both of these components are crucial to fit the yield curve as well as generate sensible economic
implications.

Our paper relates to the regime-switching literature, with the seminal paper by Hamilton (1989). Applications of this class of model in the term structure literature include Ang and Bekaert (2002), Bansal and Zhou (2002), and Dai et al. (2007). The difference is that we focus on the regime shifts in the lower bound for interest rates, which is a newly developed phenomenon.

2 Empirical evidence

Since July 2012, the ECB has lowered the deposit rate to zero, entering the zero lower bound era (see the blue line in Figure 1). They subsequently moved the policy rate to be negative, replacing the ZLB with ELB. The official level of the ELB prescribed by the central bank can be measured by the deposit rate. This section first documents a positive and significant response of government bond yields to a change in the lower bound. We then raise a puzzle: the response is larger at longer maturities.
2.1 Lower bound and 10-year yield

We first document the qualitative relationship between the lower bound and yields. We use the 10-year yield for demonstration.

Figure 2 describes the relationship between the 10-year yield and the deposit rate. Blue dots are observations, and the red line is obtained by regressing the 10-year yield on the deposit rate. A higher lower bound is associated with higher long term interest rates. For example, when the lower bound is 0, the 10-year yield is about 2\%, whereas a lower bound at -40 basis points is associated with 10-year yields around 0.

This relationship can also be captured by the following regression:

\[
y_{nt} = \beta_0 + \beta_1 r^d_t + \beta_2 X^\text{Macro}_t + e_t,
\]  

(2.1)

where \( y_{nt} \) is the yield of the zero-coupon bond with a maturity of \( n \) periods, and \( r^d_t \) is the deposit rate. \( X^\text{Macro}_t \) controls for relevant macroeconomic variables, including inflation, the ECB’s balance sheet as a percentage of GDP, industrial production (IP) growth, and

Notes: Regression coefficients and standard errors.

unemployment rate. Table 1 shows that the coefficients on the deposit rate are positive across all model specifications, and all of them are statistically significant. This indicates that the movements in the 10-year yield and the deposit rate are positively correlated even after controlling for these macro variables.

2.2 Puzzle

We next assess the results for the regression (2.1) for yields across different maturities in Figure 3. The effect is about one-for-one at the short end of the yield curve. This is intuitive: the short end of the yield curve is primarily driven by monetary policy.

However, the effect grows at longer horizons, which is counter-intuitive and puzzling. We can write a longer term interest rate as sum of the expectation and term premium components

\[ y_{nt} = \frac{1}{n}E_t(r_t + \ldots + r_{t+n-1}) + tp_{nt}, \quad (2.2) \]

where \( r_t \equiv y_{1t} \) is the one-period short rate. \( tp_{nt} \) is the term premium for the \( n \)-period yield \( y_{nt} \), and this component of the yield is not driven by monetary policy.
Figure 3: Regressing yield curve on deposit rate

*Notes:* Regression coefficients of (2.1) on the deposit rate across different models specified in Table 1. X-axis: maturity in months.

Decreasing the lower bound by 10 basis points would lower the short rate $r_t$ by the same amount. If this shock is permanent, that is, all future short rates are decreased by 10 basis points, the long term interest rate $y_{nt}$ consequently decreases by the same amount. If the shock is transitory and dies out over time, the long term interest rate $y_{nt}$ decreases by less than 10 basis points.

Results in Figure 3 contradict this basic intuition. There are several reasons that could potentially contribute to this puzzling result. First, the relationship between yields and macro variables becomes non-linear at the ELB. This is one of a few consensus reached in the literature about the ELB. Second, other factors that are important to the yield curve are not controlled for, which biases the results. Third, the regression model does not impose any economic structure across maturities, and potentially allows for arbitrage opportunities.

To reconcile the puzzle with the intuition from (2.2), we resort to a new dynamic term structure model in Sections 3 and 4, which imposes restrictions across different maturities to exclude arbitrage opportunities and addresses other concerns mentioned above.
3 A new shadow-rate term structure model

The time-varying lower bound in Figure 1 introduces new challenges for modeling the term structure of interest rates. Most existing models assume a constant lower bound. A few papers have introduced an exogenously moving lower bound. In these models, agents are myopic, and do not consider possible future changes of the lower bound. How to incorporate the forward-looking aspect into the model yet retain its tractability? This section and Section 4 propose a new term structure model that achieves these goals.

3.1 Setup

Following Black (1995), the short-term interest rate $r_t$ is the maximum function of the shadow rate $s_t$ and a lower bound. The innovation of our paper is that the lower bound for the government bond yield curve $r_t$ is time varying, and relates to the short rate as follows:

$$ r_t = \max (s_t, r_t) . \tag{3.1} $$

The shadow rate is an affine function of the latent yield factors, often labeled as “level,” “slope,” and “curvature”:

$$ s_t = \delta_0 + \delta_1 X_t, $$

whose physical dynamics follow a first-order vector autoregression (VAR):

$$ X_t = \mu + \rho X_{t-1} + \Sigma \varepsilon_t, \varepsilon_t \sim N(0, I). \tag{3.2} $$

Similarly, the Q dynamics are

$$ X_t = \mu^Q + \rho^Q X_{t-1} + \Sigma^Q \varepsilon_{t}^Q, \varepsilon_t^Q \sim N(0, I). $$
3.2 Bond prices

The no-arbitrage condition specifies that prices for zero-coupon bonds with different maturities are related by

\[ P_{nt} = E_t^Q[\exp(-r_t)P_{n-1,t+1}] \, . \]

The \( n \)-period yield relates to the price of the same asset as follows:

\[ y_{nt} = -\frac{1}{n} \log(P_{nt}). \]

Following Wu and Xia (2016), we model forward rates rather than yields for the simplicity of the pricing formula. Define the one-period forward rate \( f_{nt} \) with maturity \( n \) as the return of carrying a government bond from \( t + n \) to \( t + n + 1 \) quoted at time \( t \), which is a simple linear function of yields:

\[ f_{nt} = (n + 1)y_{n+1,t} - ny_{nt}. \]

Therefore, modeling forward rates is equivalent to modeling yields. In fact, their short ends are identical:

\[ f_{0t} = y_{1t} = r_t. \]

The new pricing formula for the forward rate with a time-varying lower bound is

\[ f_{nt} \approx \int \left( \tau_{t+n} + \sigma_n^Q g \left( \frac{a_n + b_n'X_t - \tau_{t+n}}{\sigma_n^Q} \right) \right) P_t^Q(\tau_{t+n})d\tau_{t+n}, \quad (3.3) \]

given that the factors \( X_t \) do not depend on \( r_t \), where

\[ g(z) = z\Phi(z) + \phi(z) \quad (3.4) \]
is the function approximating bond prices in the SRTSM in Wu and Xia (2016). Inside the
g function, \( a_n + b'_n X_t \) is the \( n \)-period forward rate from the Gaussian affine term structure
model. The coefficients \( a_n \) and \( b_n \) follow a set of difference equations, and their solutions are

\[
a_n = \delta_0 + \delta_1 \left( \sum_{j=0}^{n-1} (\rho^Q)^j \right) \mu^Q - \frac{1}{2} \delta_1 \left( \sum_{j=0}^{n-1} (\rho^Q)^j \right) \Sigma \Sigma' \left( \sum_{j=0}^{n-1} (\rho^Q)^j \right)' \delta_1,
\]

\[
b'_n = \delta_1 (\rho^Q)^n.
\]

In addition, \( (\tilde{\sigma}_n^Q)^2 \equiv V_t^Q (s_{t+n}) \) is the conditional variance of the future shadow rate, and

\[
(\tilde{\sigma}_n^Q)^2 = \sum_{j=0}^{n-1} \delta_1 (\rho^Q)^j \Sigma \Sigma' (\rho^Q)^j \delta_1.
\]

See Appendix B.1 for the derivation.

\( P_t^Q(r_{t+n}) \) in (3.3) is the risk-neutral probability distribution for the lower bound \( n \)-periods
later. Section 4 will specify this distribution with the following two goals. First, capture the
main features in the data. Second, preserve an analytical approximation for bond prices.

Considering a time-varying lower bound is how (3.3) differs from Wu and Xia (2016).
Specifically, the new pricing formula (3.3) prices in uncertainty associated with the future
dynamics of the lower bound. The forward rate is calculated as an average of forward rates
with known \( r_{t+n} \), weighted by the risk-neutral probability distribution of \( r_{t+n} \). If \( r_{t+n} \) were
a constant, (3.3) becomes the pricing formula in Wu and Xia (2016).

### 4 Time-varying lower bound

This section proposes a novel model for the time-varying lower bound. First, we model the
component of the lower bound that is driven by monetary policy. Due to its discrete nature,
we propose a regime-switching model. Then, we inspect the spread between the overnight
policy rate and the government yield curve. Our agents are fully forward looking, incorpo-
rating potential changes of the future lower bound into bond prices. Although our model
is more flexible in order to accommodate features in the data, it still allows an analytical approximation for bond prices. Having analytical bond prices is crucial for the tractability and better numerical behavior of the model. In Section 6, we will demonstrate our model’s ability to fit the data.

4.1 Policy lower bound

Much of the government bond yield curve is driven by monetary policy. In this section, we investigate the policy-driven component of the time-varying lower bound. We inspect empirical features of the policy rate, and use them to inform a regime-switching model.

The deposit rate $r^d_t$ in Figure 1 is a natural candidate for the policy lower bound $L^d_t$ when the economy was binding at the ELB. We formalize the concept of the policy lower bound as follows:

$$
\begin{cases}
L^d_t = 0, \text{ if not ELB} \\
L^d_t = r^d_t, \text{ if ELB},
\end{cases}
$$

and plot it in the black dotted line in Figure 1.

**Simple facts** The first empirical observation from Figure 1 is that the policy lower bound is discrete and takes multiples of -10 basis points. In the data, we have observed it takes the value of 0, -10, -20, -30, and -40 basis points. In the model, we assume its maximum value is 0 and its minimum is $-R$:

$$L^d_t \in \{0, -10, \ldots, -R\} \text{ basis points.}$$

Another observation from Figure 1 is the policy lower bound moves 10 basis points at a time, if it moves. Moreover, for most of the time, it stays constant. In the data, we only see the lower bound decrease. In the future, we expect the lower bound to eventually move
back up to zero. Hence,

\[
\mathbb{P}(\Delta_t^d = \Delta_{t-1} | \Delta_{t-1} \in \{\Delta_{t-1} - 10, \Delta_{t-1}, \Delta_{t-1} + 10\}) = p. \tag{4.3}
\]

**Momentum** Equation (4.3) captures the persistence in the policy lower bound in the sense that the lower bound could stay where it was. Another type of persistence exists in terms of whether the policy lower bound or deposit rate is moving downward or upward. For example, when a broad downward trend occurs, as we have experienced since the onset of the ELB, it is more likely to keep moving down than up. This demonstrates the momentum of the lower-bound movements. We formalize this idea by introducing \( \Delta_t \), which describes the direction in which the lower bound is moving. \( \Delta_t = \pm 1 \), where \( \Delta_t = +1 \) is the up state and \( \Delta_t = -1 \) is the down state. The lower bound \( r_t^d \) might stay constant for a period of time between two downward movements, and we still refer to this period as the down state \( \Delta_t = -1 \). More specifically, we define it as follows:

**Definition 1** When \( r_t^d > -R \), \( \Delta_t = -1 \) if \( \exists n > 0 \) such that \( r_t^d < r_{t-n}^d \) and \( r_t^d = r_{t-j}^d \forall 0 < j < n \); otherwise, \( \Delta_t = +1 \). When \( r_t^d = -R \), \( \Delta_t = \pm 1 \).

Figure 1 demonstrates the down state is persistent or has momentum. This can be extended to the up state as well. We capture this persistence with the following risk-neutral dynamics:

\[
P^Q(\Delta_t = \Delta_{t-1} | \Delta_{t-1}) = p, \tag{4.4}
\]

where \( p \approx 1 \) describes a down state is most likely followed by another down state, which is consistent with the data. \( P^Q(\Delta_t \neq \Delta_{t-1} | \Delta_{t-1}) = 1 - p \) is the probability of changing the direction.

**Conditional distribution of lower bound** Equation (4.3) and Definition 1 imply that if we are in the \( \Delta_t = -1 \) state, the lower bound can only stay where it was \( r_t^d = r_{t-1}^d \) or
move down by 10 basis points $r^d_t = r^d_{t-1} - 10$. Similarly, if $\Delta_t = +1$, then $r^d_t = r^d_{t-1}$ or $r^d_t = r^d_{t-1} + 10$. We formalize this idea by specifying the conditional transition probability $P^Q(r^d_t | r^d_{t-1}, \Delta_t)$ in Table 2. Per (4.3), the lower bound does not always move. We allow for a probability $\pi$ that the lower bound stays the same, and $\pi \approx 1$. Next, per (4.2), the lower bound is not allowed to go above 0 or below $-R$. Therefore, when $\Delta_t = -1$ and $r^d_{t-1} = -R$, all the probability mass concentrates at staying. We make $r^d_t = 0$ an absorbing state, that is, $r^d_t = 0$ if $r^d_{t-1} = 0$, to capture the long history of the lower bound at zero.

**Marginal distribution of lower bound** From (3.3), the probability distribution of interest for pricing purposes is the risk-neutral probability distribution of the lower bound $n$ periods into the future. It can be written as the sum of the joint distributions of the lower bound and directional states:

$$P^Q_t(r^d_{t+n}) = \sum_{\Delta_{t+n}} P^Q_t(r^d_{t+n}, \Delta_{t+n}),$$

and the right-hand side has the following dynamics:

$$P^Q_t(r^d_{t+n}, \Delta_{t+n}) = \sum_{r^d_{t+n-1}, \Delta_{t+n-1}} P^Q_t(r^d_{t+n}, \Delta_{t+n} | r^d_{t+n-1}, \Delta_{t+n-1}) P^Q_t(r^d_{t+n-1}, \Delta_{t+n-1}),$$

P_t^Q(r_{t+n}^d, \Delta_{t+n} | r_{t+n-1}^d, \Delta_{t+n-1}) &= P_t^Q(r_{t+n}^d | r_{t+n-1}^d, \Delta_{t+n} | \Delta_{t+n-1}) \cdot P^Q(\Delta_{t+n} | \Delta_{t+n-1}) \\ &= P^Q(r_{t+n}^d | r_{t+n-1}^d, \Delta_{t+n}) \cdot P^Q(\Delta_{t+n} | \Delta_{t+n-1}),
\end{align*}
\]

(4.7)

and the two components are defined in (4.4) and Table 2. The matrix form of the joint dynamics (4.6) is in Appendix A.

4.2 Spread

So far, we have laid out two lower bound concepts. We introduced the lower bound for the government bond \( r_t \) in Section 3. In Subsection 4.1, we built a model for its main component: the policy lower bound \( r_t^d \). In a world without frictions, these rates should be identical. In practice, they are not perfect substitutes due to some institutional details. For example, some financial institutions cannot access reserves, which creates a wedge between the two.

Figure 4 plots the time-series dynamics of the one-month short-term interest rate and deposit rate in the top panel, and their difference in the middle. At the beginning of the ELB period, the two rates were very similar to each other, as theory suggests. However, the difference grew over time. The spread was positive from mid 2013 to early 2015, and at the peak, the short rate was 20 basis points higher than the deposit rate.

Since early 2015, the short rate - deposit rate spread has become negative and has grown over time. By the end of 2016, the difference became -60 basis points. One explanation for this negative spread toward the end of our sample is that government bonds issued by countries such as Germany and France are often posted as collateral for short-term borrowing in repo markets, and excessive cash in these economies leads to scarcity of these assets.

The bottom panel of Figure 4 plots the cross section of the forward curve in December 2016. The front end of the curve was at -90 basis points, whereas the deposit rate was
Figure 4: Spread

Notes: Top panel: time-series dynamics of the one-month yield in blue solid line and deposit rate in red dashed line; middle panel: the difference between the one-month yield and deposit rate. X-axis for these two panels: time. Sample spans from July 2012 to December 2016. Bottom panel: forward curve in December 2016 in blue solid line and deposit rate in dashed red line. X-axis for this panel: maturity in months.
only -40 basis points. Note the discrepancy between government bond interest rates and the deposit rate is not limited to the very short end. Rather, it extends to all the maturities.

To capture this fundamental feature of the data, we introduce a spread into our model, and model the lower bound for the government bond as the sum of the policy lower bound and a spread\(^1\):

\[
\begin{cases}
    r_t = 0, & \text{if not ELB} \\
    r_t = r^d_t + s_p, & \text{if ELB},
\end{cases}
\]  

(4.8)

where the spread \(s_p\) follows an AR(1) with mean 0 under the risk-neutral measure:

\[
s_p = \rho s_p s_{p-1} + e_t, \ e_t \sim N(0, \sigma^2_{sp}).
\]  

(4.9)

### 4.3 Bond prices

With the dynamics of the lower bound specified in Subsections 4.1 - 4.2, the pricing formula in (3.3) becomes

\[
f_{nt} \approx \sum_{t+n} P^Q_t \left( r^d_{t+n} + c_n s_p + \sigma^Q_n g \left( \frac{a_n + b'_n X_t - r^d_{t+n} - c_n s_p}{\sigma^Q_n} \right) \right),
\]

(4.10)

where \(c_n = \rho_{sp}^n (\sigma^Q_n)^2 = (\sigma^Q_n)^2 + (\sum_{j=0}^{n-1} \rho_{sp}^j)\sigma^2_{sp}\). See Appendix B.2 for the derivation.

The integral in (3.3) is replaced by the summation in (4.10). The regime-switching dynamics for the discrete policy lower bound and the AR process for the spread together preserve the analytical approximation for the pricing formula. Having an analytical approximation is crucial for the model to be tractable and have better numerical behavior. Dynamics term structure models are often criticized for being difficult to estimate. For example, in the class of Gaussian affine term structure model which is a special case of our model when

\[^1\text{We estimated a constant lower bound using the sample from September 2004 to May 2014, and the estimate is essentially 0.}\]
and has analytical bond prices, a literature has been dedicated to improving the model’s performance: See Joslin et al. (2011), Christensen et al. (2011), Hamilton and Wu (2012b), Adrian et al. (2012), Creal and Wu (2015), and de Los Rios (2015). If we had to compute bond prices numerically, the model would behave worse.

5 Estimation

We construct 3- and 6-month-ahead and 1-, 2-, 5-, 7-, and 10-year-ahead 1-month forward rates for AAA-rated government bond yields in the Euro area; the dataset is available on the ECB’s website.\(^2\) Our sample is monthly from September 2004 to December 2016. We date the ELB period when the deposit rate is zero and below, and it starts from July 2012.

For the new part of the model detailed in Section 4, we pool information from the physical dynamics and risk-neutral dynamics together in our main specification due to the short sample. Specifically, the physical dynamics are the same as the risk-neutral dynamics specified in Section 4. This assumption will be relaxed in the extension in Subsection 6.4, and all of our main results hold.

The state variables \(r_t\), \(\Delta_t\) are measured according to (4.1) and Definition 1. Conditioning on \(r_t\), \(\Delta_t\), we express our SRTSM with a time-varying lower bound as a nonlinear state-space model. The transition equations include (3.2) and (4.9), which describe the dynamics of the latent factors. (4.10) relates the model-implied forward rate \(f_{nt}\) to the state variables. Adding measurement errors, the measurement equation for the observed forward rate \(f_{nt}^o\) becomes

\[
f_{nt}^o = \sum_{\ell = n} P_t^{Q}(r_{t+n}) \left( r_{t+n}^d + c_n s_p + \sigma_n^Q \left( \frac{a_n + b' X_t - r_{t+n}^d - c_n s_p}{\sigma_n^Q} \right) \right) + \eta_{nt}, \tag{5.1}
\]

where the measurement error \(\eta_{nt}\) is i.i.d. normal, \(\eta_{nt} \sim N(0, \omega^2)\).

The collection of parameters we estimate consists of three subsets: (1) parameters related to \(r_t\) and \(\Delta_t\), including \((p, \pi)\); (2) parameters describing the dynamics of \(s_p\), including

---

\(^2\)These forward rates map into \(f_{nt}\) in (3.3) with \(n = 3, 6, 12, 24, 60, 84, 120\).

(ρₛₚ, σₛₚ); and (3) parameters related to Xₜ, including (µ, µᵦ, ρ, ρᵦ, Σ, δ₀, δ₁). For identification, we impose restrictions on parameters in the last group similar to Hamilton and Wu (2014): (i) δ₁ = [1, 1, 1]′, (ii) µᵦ = 0, (iii) ρᵦ is diagonal with eigenvalues in descending order, and (iv) Σ is lower triangular.

We use maximum likelihood estimation with the extended Kalman filter. See Appendix C for details. In our implementation, we set −R = −100 basis points. We report maximum likelihood estimates and robust standard errors (see Hamilton (1994)) in Table 3. The eigenvalues of ρ, ρᵦ indicate the factors Xₜ are highly persistent under both measures. This finding is consistent with the term structure literature. The lower-bound dynamics are also
persistent. $\Delta_t$ has a 96% chance of staying the same, for example, from a down state to another down state. The chance for the lower bound to stay where it was is 97%. The spread $sp_t$ almost follows a random walk. Other parameters controlling level and scale are comparable to what we see in the literature.

Figure 5 plots the spread filtered from our model in blue, and compares it with two proxies constructed from the observed data. The first proxy in the red dotted line is the difference between the 3-month forward rate and the deposit rate, where three months is the shortest maturity used in our sample. They closely track each other, with a high correlation at 0.96. The second proxy takes the difference between the short rate and the deposit rate, as suggested by the model. Although the short rate is not in our information set when we estimate the model, the observed and filtered spreads are again very close to each other.

6 Economic implications

Subsection 6.1 conducts counterfactual policy analyses to see the effect of changing the ELB on the yield curve. We then show the importance of correctly specifying the lower bound
Figure 6: Impact of lowering ELB on the yield curve

Notes: Top panels: changes in the yield curve in response to lowering the ELB by 10 basis points. Bottom panels: expected changes in the lower bound. Blue lines: agents are forward looking; red dashed lines: agents are not forward looking. X-axis: maturity in months; Y-axis: interest rates in percentage points.

process in Subsection 6.2. We compare our main model as laid out in Sections 3 - 4 with alternative specifications for the lower bound. Subsections 6.3 - 6.4 discuss the implied shadow rate and term premia.

6.1 Counterfactual policy analyses

In this section, we conduct counterfactual policy analyses to study the impact of changing ELB on the yield curve. Specifically, we ask how the forward and yield curves react if we lower the ELB by 10 basis points. We conduct this experiment by explicitly holding other factors affecting the yield curve constant. Figure 6 plots reactions across three different
The responses of the yield curve from our main model are in the blue lines in the top panels. By lowering the ELB by 10 basis points, the short end of the curve subsequently decreases by 10 basis points as well. This effect is dampened when maturity increases. At the 10-year horizon, the change decays to about 6 to 8 basis points. This result is consistent with the intuition from (2.2).

We demonstrate the importance of forward-looking agents by also plotting in red what happens when agents are myopic. The effect on the longer end of the yield curve is less when agents are forward looking, because they expect the lower bound to revert to its unconditional mean in the long run, whereas naive agents think the 10-basis-point change in the lower bound is permanent. The expected changes in the lower bound are illustrated in the bottom panels.

6.2 Model comparison

Alternative specifications  We show the importance of our new modeling ingredients by comparing our main model $M_{\text{main}}$ with alternative model specifications described in Table 4. Models $M_{BM-TV}$, $M_{BM-0}$, and $M_{BM-40}$ are the benchmarks in the literature. None of them allow (1) a regime-switching process for the policy lower bound, (2) a non-constant spread between the policy rate and the yield curve, or (3) forward-looking agents in terms of future changes in the lower bound.

$M_{BM-TV}$ does allow an exogenously varying lower bound tracking the deposit rate, and is consistent with the online implementation of Wu and Xia (2016) for the Euro zone, and similar to Lemke and Vladu (2016) and Kortela (2016). $M_{BM-0}$ and $M_{BM-40}$, on the other hand, have a constant lower bound, consistent with most SRTSM papers on the US yield curve. For example, see Christensen and Rudebusch (2014), Wu and Xia (2016), and Bauer and Rudebusch (2016). The difference between them are the level of the lower bound: it is naively chosen at 0 for $M_{BM-0}$, and -40 basis points for $M_{BM-40}$ as the lowest point of the

Notes: Top panel: full sample from September 2004 to December 2016; bottom panel: ELB sample from July 2012 to December 2016. First column: our main model \( M_{\text{main}} \); second column: benchmark model \( M_{BM-TV} \) with exogenously varying lower bound; third column: benchmark model \( M_{BM-0} \) with a constant lower bound at zero; fourth column: benchmark model \( M_{BM-40} \) with a constant lower bound at -40 basis points; fifth column: \( M_{RS} \) without spread; Conditional log likelihood, conditioning on the observed \( \Delta_{1:T} \), \( r_{1:T} \), and corresponding AIC and BIC are reported for the full sample. Measurement errors are in basis points, and computed as the root-mean-square errors between observed and model-implied forward rates with maturities from 3 months to 10 years. We highlight the smallest measurement errors, AIC and BIC, and the highest log likelihood value.

To single out the contributions of the regime-switching policy lower bound and the spread, we also introduce an intermediate model \( M_{RS} \). It is our main model excluding the spread: \( sp_t = 0 \). The comparison between this model and the benchmark models tells us how much improvement comes from the regime-switching policy lower bound alone. The difference between this model and our main model further shows the contribution of adding the spread. Details for these models can be found in Appendix C.3.

**Performance of our main model** Table 5 compares these models in terms of log like-
Notes: Left panel: average observed and fitted forward curve in the year 2006; right panel: average observed and fitted forward curve in the year 2016; blue dots: observed data; red solid line: our main model $M_{\text{main}}$; cyan dotted-dashed line: benchmark model $M_{BM-TV}$ with exogenously varying lower bound; green dotted line: benchmark model $M_{BM-0}$ with a constant lower bound at zero; magenta dashed line: benchmark model $M_{BM-40}$ with a constant lower bound at -40 basis points; black dotted line: $M_{RS}$ without spread. X-axis: maturity in month; Y-axis: interest rates in percentage points.

likelihood values, information criteria, and measurement errors. Our main model $M_{\text{main}}$ yields the highest likelihood value. It also has the smallest AIC and BIC, where the information criteria penalize overparameterization. These results indicate that the higher log likelihood is not artificially inflated by additional flexibility. Rather, the new ingredients of the model do improve the fitting in a meaningful way. Our main model also provides the best overall fit to the forward curve with the smaller measurement errors. All the evidence points to the conclusion that the data favor our main model over these alternative model specifications.

Figure 7 provides some visual evidence by comparing the observed data in blue dots with various model-implied curves. The left panel plots the average forward rates in 2006 when the ELB was not binding, and all the models fit the data similarly well. The right panel shows that in 2016, when the ELB was binding and the spread was over 20 basis points on average, our preferred model $M_{\text{main}}$ fits the short end of the term structure significantly.
Discussion on choice of exogenous lower bound  For the benchmark models existing in the literature, although the lower bound is exogenously given, its choice is not innocuous. For example, the only difference between $M_{BM-0}$ and $M_{BM-40}$ is the level of the constant lower bound. However, their performances differ dramatically. Their log likelihood differ by over 400. The measurement errors on the short of the curve end at the ELB for $M_{BM-0}$ is over 33 basis points, whereas they are about 12 for $M_{BM-40}$. The explanation is intuitive: the model $M_{BM-0}$ sets the lower bound artificially at 0, and it does not allow yields or forward rates lower than 0. Any observed negative yield is considered a measurement error. So, for example, in Figure 7, the average forward rates for maturities from 3 months to 2 years are around -60 basis points in 2016. The model-implied curve in green, however, is stuck at 0, and obviously is not able to fit the data.

Although all the benchmarks from the literature are not doing nearly as well as our main model, among them, the model with an exogenously moving lower bound $M_{BM-TV}$ does the best, based on likelihood and information criteria. In terms of measurement errors, $M_{BM-TV}$ fits the longer end better, whereas the model with a constant lower bound at -40 basis points $M_{BM-40}$ fits the shorter end better.

Importance of modeling components  The comparison between the benchmark model $M_{BM-TV}$ and the intermediate model $M_{RS}$ demonstrates the importance of forward-looking agents. The paths of the lower bound are the same in the two models. The difference lies in how agents form expectations: agents are fully forward-looking in $M_{RS}$, anticipating future changes in the lower bound, and incorporate this information into their pricing decisions. In $M_{BM-TV}$, agents do not learn from experience and always think the lower bound will stay at the current level indefinitely even after seeing it move repeatedly.

The model $M_{RS}$ with forward-looking agents has a much higher likelihood, and lower information criteria and measurement errors. The right panel of Figure 7 shows that although
it is not able to fit the three-month-ahead forward rate, it does a better job fitting the six-month-ahead and one- to two-year-ahead forward rates, because the forward-looking aspect allows the curve to go down when maturity increases. This is not feasible in the benchmark model $M_{BM-TV}$. The implied forward curves in cyan stay flat, missing the entire short end.

Both Table 5 and Figure 7 show that compared to $M_{RS}$, $M_{main}$ is doing better in terms of all the dimensions we investigate. This comparison demonstrates the importance of the time-varying spread, which allows the short end of the forward curve to be decoupled from the policy lower bound. This data feature is evident in Figure 4. For example, in 2016, the policy lower bound was at -0.4%, whereas the average three-month-ahead forward rate was less than -0.6%. Without a spread, $M_{RS}$ has difficulty fitting the three-month maturity.

The overall conclusion is that both modeling components are crucial to model the term structure of the Euro area government bond yield curve.

### 6.3 Shadow rate

The shadow rate is an object of interest from this model. See Bullard (2012), Altig (2014), Hakkio and Kahn (2014), and Wu and Zhang (2016) for discussions on its potential usefulness.
for summarizing monetary policy. Figure 8 plots the filtered shadow rate from our main model $M_{main}$ in the solid blue line, together with the deposit rate in the dashed red line, the refinancing rate in the dotted-dashed yellow line, and the short rate in the dotted purple line. When interest rates were higher, the shadow rate tracked the dynamics of the refinancing rate and short rate, which are the policy rate and the short end of the yield curve, respectively. When the deposit rate dropped to 0.25% in 2009 for the first time, the shadow rate dipped negative for a brief period of four months. At the end of 2011, the deposit rate went back down to 0.25% after eight months at higher levels, and the shadow rate has since become negative. This observation implies that although the ELB was not officially binding, it was practically binding in the low interest rate environment.

Since the deposit rate was lowered to zero in July 2012, the variation in the policy rates or the short rate has been limited, whereas the shadow rate has displayed its own dynamics. When the deposit rate was at 0, the shadow rate fluctuated between 0 and -1%. The shadow rate has trended down since the ECB introduced the negative interest rate policy intending further easing. When the deposit rate dropped from 0 to -40 basis points, the shadow rate decreased from around -1% to almost -5%.

6.4 Term premium

Term premium is one of the focal points for the term structure literature. See, for example, Duffee (2002), Wright (2011), Bauer et al. (2012, 2014), and Creal and Wu (2016). We compute the 10-year term premia for the Euro area from our main model, and plot them in blue lines in Figure 9.

Forward and yield term premia display similar dynamics. Term premia were higher for the first part of the sample, and have trended down since 2009. At the ELB, we observe some negative term premia. This observation can mainly be attributed to the QE programs, which purchase longer-term government bonds and reduce yields through the term premium channel. For empirical evidence, see Gagnon et al. (2011), Krishnamurthy and Vissing-
Figure 9: 10-year term premia

Notes: Left panel: forward term premia; right panel: yield term premia. Blue solid lines: term premia from our main model; red dashed lines: term premia from the extended model; yellow dotted lines: the regime-switching portions of term premia from the extended model. X-axis: time; Y-axis: interest rates in percentage points. Sample spans from September 2004 to December 2016.

Jorgensen (2011), and Hamilton and Wu (2012a).

A new question in our context is whether the time variation of the policy lower bound incurs an additional term premium on the longer-term yield or forward rate. To address this question, we extend our main model by allowing the physical and risk-neutral dynamics for the regime-switching part to be different. Specifically, the two dynamics follow the same process as described in Subsection 4.1, but with different parameters: \((p, \pi)\) for the physical dynamics, and \((p^Q, \pi^Q)\) for the risk-neutral dynamics.

The yellow dotted lines in Figure 9 plot the regime-switching portions of the term premia, which are essentially zero. This result attributes almost all of the term premia to uncertainty about the underlying latent factors. Moreover, the overall term premia in the extended model in red dashed lines are essentially the same as those in our main model. Hence, the term premia from our main model are robust, and this extension does not make an economic difference.

7 Conclusion

We proposed a new shadow-rate term structure model, which captures the time-varying lower bound that has emerged recently in Europe and Japan. Two main aspects contribute to this time-varying lower bound. First, the deposit rate has moved in a discrete negative
grid, and we capture its dynamics with a regime-switching model. In our model, agents are forward looking, anticipate future changes in the deposit rate, and price them into bond prices. Second, a time-varying spread exists between the policy lower bound and the government yield curve, capturing some institutional details. We find both ingredients crucially contribute to the fit of the forward curve and yield curve. Compared to alternative specifications for the lower bound, including the ones proposed in the literature, our new model fits the data the best. Our counterfactual policy analyses show a 10-basis-point decrease in the ELB lowers the short end of the yield curve by the same amount. The effect decays as the maturity increases, and it amounts to 6 to 8 basis points at the 10-year horizon. The shadow rate fluctuated between 0 and -1% when the deposit rate was at 0. When the deposit rate moved from 0 to -40 basis points, the shadow rate dropped from -1% to -5%. Term premia were higher between 2004 and 2008. It has trended down since 2009, with negative numbers at the ELB, potentially due to QE purchases.

0 & 0 & 0 & 0 & \ldots & 0 & 1
\end{bmatrix}.
\]
Appendix B  Deriving pricing formula

Appendix B.1  General form

As shown in Wu and Xia (2016), the forward rate is

\[
f_{nt} \approx E_t^Q \left[\sum_{j=1}^{n} r_{t+j} - \frac{1}{2} \left( \sum_{j=1}^{n-1} r_{t+j} \right) \right] \tag{B.1}
\]

\[
\approx E_t^Q (\max(s_{t+n}, r_{t+n})) - P_t^Q(s_{t+n} \geq r_{t+n}) \times \frac{1}{2} \left( \sum_{j=1}^{n} s_{t+j} - \sum_{j=1}^{n-1} s_{t+j} \right).
\]

The right-hand side equals

\[
\int \left[ -P_t^Q(s_{t+n} \geq r_{t+n}) \times \frac{1}{2} \left( \sum_{j=1}^{n} s_{t+j} - \sum_{j=1}^{n-1} s_{t+j} \right) \right] \, d\xi_{t+n}.
\]

According to Wu and Xia (2016), the expression inside the integral conditioning on the lower bound equals

\[
r_{t+n} + \sigma_n^Q g \left( \frac{a_n + b_n' X_t - r_{t+n}}{\sigma_n^Q} \right).
\]

Hence, we obtain (3.3).

Appendix B.2  Main model

First,

\[
P_t^Q(s_{t+n} - s_{p,t+n}) \sim N(\bar{a}_n + b_n' X_t - c_n s_{p,t}, (\sigma_n^Q)^2),
\]

where \(\bar{a}_n \equiv \delta_0 + \delta_1 \left( \sum_{j=0}^{n-1} (\rho^Q)^j \right) \mu^Q\). The first term on the right-hand side of (B.1) is

\[
E_t^Q(r_{t+n}) = E_t^Q[\max(L_{t+n}', s_{t+n})] = E_t^Q[\max(L_{t+n}', s_{t+n} - s_{p,t+n})] + E_t^Q(s_{p,t+n})
\]

\[
= \sum_{L_{t+n}'} P_t^Q(L_{t+n}') E_t^Q[\max(L_{t+n}', s_{t+n} - s_{p,t+n})] + E_t^Q(s_{p,t+n})
\]

\[
= \sum_{L_{t+n}'} P_t^Q(L_{t+n}') \left( L_{t+n}' + \sigma_n^Q g \left( \frac{\bar{a}_n + b_n' X_t - c_n s_{p,t} - L_{t+n}'}{\sigma_n^Q} \right) \right) + s_{p,t},
\]

where the derivation for the last equal sign follows Wu and Xia (2016).
where the first approximation sign and last equal sign follow Wu and Xia (2016).

Adding them together yields (4.10):

\[
\begin{align*}
f_{nt} & \approx \sum_{\tau_{t+n}^d} P_t^Q(\tau_{t+n}^d) \left( \frac{\sigma_n^Q g \left( \frac{a_n + b_n' X_t - c_n s_{pt} - \tau_{t+n}^d}{\sigma_n^Q} \right)}{\frac{a_n + b_n' X_t - c_n s_{pt} - \tau_{t+n}^d}{\sigma_n^Q}} + c_n s_{pt} \right) \\
& = \sum_{\tau_{t+n}^d} P_t^Q(\tau_{t+n}^d) \left( c_n s_{pt} + \frac{\sigma_n^Q g \left( \frac{a_n + b_n' X_t - c_n s_{pt} - \tau_{t+n}^d}{\sigma_n^Q} \right)}{\frac{a_n + b_n' X_t - c_n s_{pt} - \tau_{t+n}^d}{\sigma_n^Q}} \right),
\end{align*}
\]

where the approximation follows Wu and Xia (2016).

**Appendix C**  Estimation

**Appendix C.1** Likelihood for observed state variables

The observed state variables are \((\tau_{t}^d, \Delta_t)\). The likelihood for \(\tau_{t}^d\) and \(\Delta_t\) is

\[
P(\tau_{2:T}^d, \Delta_{2:T} | \tau_{1}^d, \Delta_1) = \prod_{t=2}^{T} P(\tau_{t}^d, \Delta_t | \tau_{t-1}^d, \Delta_{t-1})
\]

\[
P(\tau_{1}^d, \Delta_1) = P(\tau_{1}^d, \Delta_1 | \tau_{1-1}^d, \Delta_{1-1})
\]

\[
P(\tau_{T}^d, \Delta_T | \tau_{T-1}^d, \Delta_{T-1}) = P(\tau_{T}^d, \Delta_T | \tau_{T-1}^d, \Delta_{T-1})
\]

\[
P(\tau_{1}^d, \Delta_1 | \tau_{1-1}^d, \Delta_{1-1}) = p^{N_1}(1 - p)^{T-1-N_1} \pi^{N_2}(1 - \pi)^{(\tilde{T}-N_2)},
\]

where \(N_1\) is the number of periods that \(\Delta_t\) does not change, \(N_2\) is the number of periods that \(\tau_{t}^d\) does not change, \(T\) is the total number of periods, and \(\tilde{T}\) is the number of periods \(\tau_{t}^d \neq 0\). The log likelihood value for \((\tau_{t}^d, \Delta_t)\) is

\[
\mathcal{L}_1 = \log(P(\tau_{2:T}^d, \Delta_{2:T} | \tau_{1}^d, \Delta_1)) = N_1 \log(p) + (T - 1 - N_1) \log(1 - p) + N_2 \log(\pi) + (\tilde{T} - N_2) \log(1 - \pi).
\]
The conditional log likelihood is 
\[ H \]
according to
\[ \hat{X} \]
with
\[ \hat{P} \]
and
\[ \hat{\pi} \]
Appendix C.2 Extended Kalman filter

Define \( X_t \equiv [X_t', s_{pt}]' \). The transition equations for latent factors \( X_t \) are in (3.2) and (4.9). Stack the observation equation (5.1) for all seven maturities:

\[ F_t^o = F \left( X_t, \xi_t^d, \Delta_t \right) + \eta_t \quad \eta_t \sim N(0, \omega^2 I_7). \]

Approximate the conditional distribution of \( X_t \) with \( X_t|F_{1:t}, \xi_t^d, \Delta_{1:t} \sim N(\hat{X}_t|t, P_{t|t}) \). Initializing with \( \hat{X}_{0|0} = (I_4 - \bar{\rho})^{-1}\bar{\mu} \) and \( \text{vec}(P_{0|0}) = (I_{16} - (\bar{\rho} \otimes \bar{\rho}))^{-1}\text{vec}(\hat{\Sigma}\hat{\Sigma}) \), we update \( \hat{X}_{t|t} \) and \( P_{t|t} \) recursively according to

\[
\begin{align*}
\hat{X}_{t|t-1} &= \bar{\mu} + \bar{\rho} \hat{X}_{t-1|t-1}, \\
P_{t|t-1} &= \bar{\rho} P_{t-1|t-1} \bar{\rho} + \hat{\Sigma} \hat{\Sigma}', \\
\hat{F}_{t|t-1} &= F(\hat{X}_{t|t-1}, \xi_t^d, \Delta_t), \\
H_t &= \left( \frac{\partial F(X_t, \xi_t^d, \Delta_t)}{\partial X_t'} \right|_{X_t = \hat{X}_{t|t-1}}')', \\
K_t &= P_{t|t-1} H_t (H_t' P_{t|t-1} H_t + \omega^2 I_7)^{-1}, \\
\hat{X}_{t|t} &= \hat{X}_{t|t-1} + K_t (F_t^o - \hat{F}_{t|t-1}), \\
P_{t|t} &= (I_4 - K_t H_t') P_{t|t-1},
\end{align*}
\]

where \( H_t' \) stacks \( \sum r_{t+n} \phi_{t+n}^P \left( \frac{a_n + [b_n', c_n]}{\sigma_n^P} \right) \times [b_n', c_n] \) for all maturities, and

\[
\begin{align*}
\bar{\mu} &= \begin{bmatrix} \mu' \\ 0 \end{bmatrix}, \\
\bar{\rho} &= \begin{bmatrix} \rho' & 0_{3 \times 1} \\ 0_{1 \times 3} & \rho_{sp} \end{bmatrix}, \\
\hat{\Sigma} &= \begin{bmatrix} \Sigma & 0_{3 \times 1} \\ 0_{1 \times 3} & \sigma_{sp} \end{bmatrix}.
\end{align*}
\]

The conditional log likelihood is

\[
\mathcal{L}_2 = \log(P(F_{2:T}^o | F_{1:T}^o, \xi_{2:T}^d, \Delta_{2:T}))
\]

\[
= - \frac{7(T - 1)}{2} \log 2\pi - \frac{1}{2} \sum_{t=2}^{T} \log|H_t' P_{t|t-1} H_t + \omega^2 I_7|
\]

\[
- \frac{1}{2} \sum_{t=2}^{T} (F_{t}^o - F(\hat{X}_{t|t-1}, \xi_{t}^d, \Delta_t)' (H_t' P_{t|t-1} H_t + \omega^2 I_7)^{-1} (F_{t}^o - F(\hat{X}_{t|t-1}, \xi_{t}^d, \Delta_t)).
\]

Notes: Top panel: observation equations for alternative model specifications, which are components of $F (X_t, r^d_t, \Delta_t)$; bottom panel: derivatives, components of $H_t$.

The likelihood of the model is the sum of the two components:

$$\mathcal{L} = \log(P(F_{2:T}^d, r^d_{2:T}, \Delta_{2:T}| F_{1:T}^d, r^d_{1:T}, \Delta_1))$$

$$= \mathcal{L}_1 + \mathcal{L}_2.$$ 

Appendix C.3 Alternative models

None of the alternative models allows a spread: $sp_t = 0$. Hence, $X_t = X_t$, and $\hat{\mu} = \mu$, $\hat{\rho} = \rho$, and $\hat{\Sigma} = \Sigma$. Observation equations and their derivatives are described in Table C.1. $\mathcal{L}_1$ only applies to $M_{RS}$, and is 0 for all the benchmark models.
